Greater Forearm Blood Flow is Associated with Higher Physical Activity in Older Individuals

Duvall, PK., Coulbourn T., Dobrosielski, DA., Knuth, ND. Towson University, Towson, Maryland.

Aging is associated with increased risk for cardiovascular disease (CVD), in part, because there is an age-related decline in vascular function. Increased physical activity has been shown to improve vascular function and protect against the development of CVD; however, the association between physical activity and vascular function in older adults is not well known. PURPOSE: Examine the relationship between objectively measured physical activity levels and forearm blood flow in a group of older men and women.

METHODS: Resting arterial inflow and reactive hyperemic blood flow (RHBF) of the left forearm was measured in 48 participants of the Longitudinal Aging Study at Towson (LAST; 54% male, mean age 69, range 46-91) using venous occlusion plethysmography. Physical activity energy expenditure (PAEE) was assessed over 7 days using an Actigraph Link accelerometer worn on the non-dominant wrist. Dual energy X-ray absorptiometry was used to quantify body composition. The association between blood flow and physical activity was modeled using linear regression, with PAEE as a predictor adjusting for age, fat mass and fat-free mass. RESULTS: Mean RHBF was 19.5 ± 6.0 mL•100mL tissue⁻¹•min⁻¹ (range 8.1-32.3 mL•100mL tissue⁻¹•min⁻¹), and mean PAEE per day was 1442 ± 574 kcals (range 328-3249 kcals). In the adjusted model, higher RHBF was positively associated with PAEE (β = 0.003, p = 0.026), indicating that blood flow was 0.3 mL•100mL tissue⁻¹•min⁻¹ higher for each 100 kcal increase in PAEE.

CONCLUSION: Physical activity is a significant predictor of RHBF in older populations, suggesting that a greater degree of physical activity is related to better overall vascular health. Therefore, increased physical activity in the aging population may be beneficial in reducing the risk of developing CVD.
